Autophagy Overview

Autophagy is the process of self-cannibalization of cellular proteins or organelles. It plays a critical role in cellular homeostasis by scavenging macromolecules in response to nutrient deprivation and by facilitating the removal of misfolded protein aggregates. During the process, the targeted constituents are wrapped up by isolating vesicles called autophagosomes. The autophagosome is a double-membrane vesicle formulated through the process triggered by LC3 and Atg16L-Atg5-Atg12 complex, in conjugation with SQSTM1 (p62) that mediates salvage enclosure. Following by the fusion of lysosome, the salvages then proceed to degradation and recycling.

Despite its simplicity, accumulating studies have demonstrated autophagy as a key process in regulating many different diseases, including neurodegeneration, cardiac myopathy, autoimmune disease and cancer. The role of autophagy in cancer is complex and paradoxical. While autophagic deficiency has been shown to promote tumorigenesis in animal models, autophagy may actually support tumor growth by enhancing cancer cell survival in the face of nutrient depletion or accumulation of toxic molecules.

Selective Autophagy

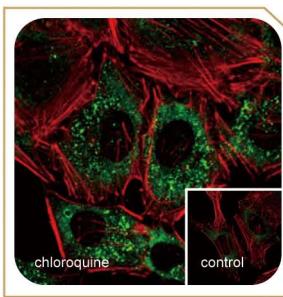

Selective autophagy refers to the selective degradation of unwanted constituents such as dysfunctional mitochondria (mitophagy), lipid droplets (lipophagy), abnormal protein aggregates (aggrophagy), and invading pathogens (xenophagy). They are important homeostatic control systems and involved in basal constitutive autophagy capable of being altered by various stressors. Defect of selective autophagy has been implicated in various physiological disorders, including cancer. But the underlying mechanisms are not fully understood.
